MARKERS OF VIRAL HEPATITIS IN HAEMOPHILIACS

*NAUMAAN MALIK, AND **ZAHID HUSSAIN

*Department of Pathology KEMC, and **Department of Pathology SIMS, Lahore

Seroprevalence of Hepatitis B surface antigen (HbsAg) and anti-HCV IgG was determined in 100 persons with Haemophilia (PWH), registered with Haemophilia Patient Welfare Society (HPWS), Lahore Zone, Pakistan. The study shows that 4% were positive for HBsAg. However, there was a high level of anti-HCV seropositivity (56%) in our PWH, including many patients in younger age groups. When compared with figures from PWH in other regions of Asia like 23% in Western India, 33% in Sri Lanka and 1 5% of those in Iran, this figure is one of the highest. This rate is a reflection of the same rising trend in our population that is now exceeding 10%. The practice of unscreened blood/blood-products transfusions in the backdrop of high prevalence of HCV in our population is responsible for high figures seen in PWH. The need is to increase awareness amongst the patients, health care workers and policy makers about the transfusion associated viral infections in a group of patients who already had a hereditary disorder of severe nature.

People with haemophilia (factor VIII and IX deficiency) and other clotting factor deficiencies are particularly at risk of acquiring blood borne hepatitis virus infections i.e hepatitis B virus (HBV) and hepatitis C virus (HCV) through transfusion with unscreened blood and blood products. Even in developed world there is a significant incidence of these infections among the patients who had received clotting factor products before 1992¹. This risk is higher in the developing world due to lack of strict regime for screening of blood and its products before transfusion². The need for screening blood for viral markers may be overlooked in an emergency setting where either testing facilities are not available or cannot be afforded by the patient. In Pakistan, majority of PWH cannot have the luxury of having highly purified plasma derived or recombinant factor concentrates for prophylaxis and for them blood transfusion remains the mainstay of management. Thus the chances of becoming infected with any of these viruses increase with the number of transfusions. With this in view, we set out to determine the seroprevalence rates for the two markers of viral hepatitis in our PWH and compare this with recently published data.

PATIENTS AND METHODS

This was a single center retrospective study involving patients registered since 1996 with HPWS, Lahore zone (HPWS is affiliated with World Federation of Haemophilia). After registration, patients were diagnosed as having haemophilia, von Willebrands disease (vWD) or other clotting factor deficiencies and then categorized as having mild, moderate or severe deficiency according to standard guidelines³. Serum samples for viral markers were drawn from PWH at the time of registration and then tested at different times afterwards. First 100 people for whom results of viral screening were complete, were included in the study. Screening was carried out by ELISA (Enzyme linked immunosorbent assay) technique. The sera were tested by 2nd and 3rd generation ELISA (Abbot and Murex).

RESULTS

The age of the patients included in this study ranged between 1 and 47 years with age break-up as shown in table 1. The most common diagnosis in 65% patients was Haemophilia A, followed by 19% patients for vWD and 9% for Haemophilia B (Table 2).

Table 1:	Age range of PWH and other coagu-
	lation disorders ($n = 100$).

Age range (years)	Percentage
0-10	34
11-20	21
21-30	21
31-40	08
41-50	02

The results for viral markers revealed that out of 100 PWH 4% tested positive for HBsAg (Table 3). In this group, two patients were 1 and 3 years old and the other two were 22 and 23 years old. The percentage of PWH testing positive for antibodies to HCV was 56%. The age break up is shown in Table-4 with all age ranges seen infected.

Table 2: Break-up of coagulation disorders (n = 100).

Type of coagulation disorder	Percentage
Haemophilia A	65
Von Willebrand Disease	19
Haemophilia B	09
Factor Vll Deficiency	02
Factor 1 Deficiency	02
Factor X Defiency	01

Table 3: Seroprevalence of markers (n = 100).

Viral Marker	Percentage
HBsAg	04
Anti-HCV antibodies	56

 Table 4: Age range of anti-HCV positive PWH (n-56).

Age Range	Percentage
0-10	14
11-20	21
21-30	25
31-40	11
41-50	02
Not recorded	15

DISCUSSION

Major source of viral infection in PWH has been the infected unscreened blood or blood clotting agents. Heat treatment for viral inactivation was introduced in mid *80's* for blood clotting agents⁴. In the UK, all haemophiliacs who had received blood products before this time contracted HCV and it has been suggested that almost one third would also be infected with HIVs⁵. However in Indian subcontinent these clotting agents have not been used because of inaccessibility and prohibitive cost for majority of patients⁶.

Four percent of our PWH had evidence of chronic infection with HBV. Two of the patients

were children aged 1 and 3 years. It is not possible to clarify if both got infected perinatally from their mothers or as a result of a contaminated blood transfusion. In either case, both infections could have been prevented by timely administration of HBV vaccine.

As for HCV, situation is quite the opposite from HBV. More than half of our PWH are already infected with HCV, that is one of the highest figures when compared with other studies that have been published recently⁶⁻¹⁰. A study by Ghosh et al reported a figure of 23% anti-HCV seropositivity for the Western Indian haemophiliacs⁶. In a separate study from Iran, anti-HCV was found in 15% of PWH against a prevalence of 0.59% in their healthy blood donor control group⁷. In Sri Lanka 33% PWH had evidence of infection with HCVs⁸. A Brazilian group found out that 44% of their PWH were infected with HCV⁹ and in Gameca 41% haemophiliacs had evidence of infection with HCV¹⁰.

In our study we were unable to include controls from healthy population for the viral markers as this was a retrospective analysis. For this reason, figures from other studies were considered. In a study by Usman et al, 4.2% of 6000 prospective military recruits were found positive for HBsAg and 4.3% for anti-HCV antibody¹¹. A report from Karachi found 4.8% healthy donors out of 560 positive for HBsAg and 1.8% carrying anti-HCV antibodies¹². Other anti-HCV data from Lahore found anti-HCV seroprevalence to be in the range of 10% in general population that was not considered to be at high risk for acquiring HCV¹³.

The HCV epidemic in our general population has already become a major public health problem and PWH are even worse affected. We should treat this situation as a priority and try to achieve the goal of providing viral marker screened donor blood for our PWH. We would need resources and proper health planning to manage our PWH and HCV infected population in the community as HCV related deaths are expected to triple over next two decades¹⁴. Becoming responsible for greater mortality than HIV infections. The measures have to be directed towards provision of safe blood and its products to everyone and to check the increase in spread of HCV infection in general population through awareness compaign on war footing. This will have a favourable impact on controlling the spread of HCV infection in our PWH as well.
